MEDICAL IMPLANTTechnical field of the invention

The present invention relates generally to the field of medical implants. More specifically, the present invention relates to an apparatus for providing a signal
5 representing the status of a sensor in a medical implant.

Background of the invention

Ever since the introduction of rate responsive im-
planted cardiac stimulators, a number of different para-
10 meters have been used for determining the activity level of the patient, which in turn is used for controlling the rate at which the heart of a patient is to be stimulated by the pacemaker. One of the most common sensors used is the piezoelectric accelerometer.

15 Another form of sensor is the intracardiac piezoelectric pressure sensor.

Unlike the piezoresistive and piezocapacitive sensors piezoelectric sensors are not energy consuming, on the contrary they generate their energy themselves.
20 Piezoelectric sensors are also arranged to alter the mechanical stress of the piezoelectric material in response to a change of loads emanating from for instance an acceleration of a seismic mass or from a change in pressure acting on the sensor. This results in a
25 transport of electrons or electrical charges within the material, which provides a change in voltage across the piezoelectric sensor. This voltage corresponds to the load to which the sensor is subjected.

A problem related to measuring the voltage across a
30 piezoelectric sensor is the leakage of charges that

occurs, negatively affecting the accuracy of the measurements. In an attempt to solve this problem, use has been made of a voltage amplifier having very high input impedance. This requires, however, a very large
5 resistance component, which is undesired within a medical implant. Furthermore, the problem related to leaking charges is still not completely eliminated, and the use of a memory function of some sort would be required. The problem of leaking charges is of particular interest when
10 the piezoelectric sensor is subjected to relatively small changes in load over long time periods, such as small changes of pressure over a long time or changes in posture.

An object of the present invention is to provide a
15 method and apparatus for determining the status of a piezoelectric sensor that takes the leakage of charges mentioned above into account.

A further object of the present invention is to improve the possibilities of evaluating the status of a
20 piezoelectric sensor.

Summary of the invention

These objects are achieved in accordance with the present invention having the features found in the main
25 claim and the preferred embodiments found in the dependent claims.

The invention is based on the insight of at least almost continuously detecting status related sensor output changes and based thereupon generating a signal
30 representing the actual status of a sensor. Advantageously, said signal is generated by integration of said sensor output changes.

Preferably, use is made of a sensor of the type in which status changes generate changes regarding electri-

cal charges in the sensor. Thus, the sensor is suitably of the piezoelectric type.

In accordance with a preferred aspect of the invention, positive and negative charges generated by the sensor, as more closely discussed below, are substantially continuously detected and removed from the sensor, thereby keeping the output voltage of the sensor at a substantially constant zero level, while at the same time providing an output current which can be the basis for an integration in order to produce said signal.

According to an embodiment of the invention, this can be accomplished by connecting the charge-producing sensor to a circuit having the characteristics of an input impedance that is extremely low or redundant. As a result, charges generated by the piezoelectric sensor will immediately leak to, or be collected or removed by, the connected circuit. This also means that there will be no problem with uncontrolled leakage of charges from the sensor, as is the case in the prior art.

As indicated above, a change of load generates a change of charges in a sensor of the piezoelectric type, all charges generated being collected, i.e. detected and removed from the piezoelectric sensor, by the connected circuit. A change of load can be either positive or negative. A positive change of load will generate an internal transport of charges in a direction opposite that caused by a negative change of load. Furthermore, if a transport of charges in one direction generates a positive voltage across the piezoelectric sensor, a transport of charges in the opposite direction generates a negative voltage. Hence, for restoring a zero voltage level across the sensor from a positive voltage level, there must be a transport of "actual" charges from the sensor, while for restoring a zero level from a negative

voltage, there must be a transport of "actual" charges from the connected circuit to the sensor.

In accordance with the above, the actual charges supplied to the sensor for restoring a zero level will
5 hereinafter be referred to as collected or removed negative charges, and the resulting current will be referred to as a negative current. Correspondingly, the actual charges removed from the sensor will be referred to as positive charges, and the resulting current as a
10 positive current. Therefore, both the supply and the removal of charges to and from the sensor will hereinafter be referred to as a collection of charges, wherein a supply of charges to the sensor will be referred to as a collection of negative charges, and a
15 removal of charges from the sensor will be referred to as a collection of positive charges.

The charges generated in a sensor of the type discussed correspond to the load (e.g. acceleration and/or gravitational force or pressure) to which the
20 sensor is subjected. Accordingly, each generated charge represents a certain change of load. A greater change of load generates more charges; a more rapid change of load provides a more rapid generation of charges; and an change of load in one direction generates positive
25 charges and an change of load in the opposite direction generates negative charges (in accordance with the above stated definition of positive and negative charges). Hence, the electric charges generated by the sensor per time unit, i.e. electric current, correspond to the
30 amount and the direction of the change of load and, hence, to the time derivative of the load to which the sensor is subjected.

The charges generated by a piezoelectric sensor, as described above, are provided to a circuit for detecting

The circuit for receiving the current (detecting and removing the charges) is, according to the invention, arranged to integrate said current, i.e. to quantify and to cumulate the charges generated by the sensor. Accordingly, the resulting value from this integration will represent the net amount, i.e. considering the sign of the generated charges, of charges generated by the sensor. Thus, the integrated value, or signal, will be directly representative of the load to which the sensor currently is subjected. Said integrated value can therefore be seen as a re-creation of the voltage that would have existed in the sensor, provided that there would have been no leakage or deliberate removal of charges at all. Thus, the present invention solves the problem regarding obtaining an absolute value representative of the level of for instance a constant acceleration or gravitational force or pressure by the use of a piezoelectric type sensor.

25 As stated above, the restoring in the sensor of a
zero level from a negative voltage level would require a
supply of charges from the connected circuit to the
sensor. According to an embodiment of the invention, the
supply of charges can be provided by connecting a
30 constant direct current, hereinafter referred to as a DC
signal, to the sensor and the circuit. If the magnitude
of the DC signal exceeds the possible maximum magnitude
of the positive and the negative sensor current, the
charges or the current supplied to the sensor for

restoring the zero level will be provided by the added DC signal. As a result, the connected circuit will be provided with a combined signal, said combined signal being the sum of the DC signal and the sensor current.

- 5 The combined signal will, e.g., have the magnitude of the DC signal when the sensor is not affected by a change in acceleration and/or gravitational force or pressure; a magnitude greater than the DC signal when the sensor is affected by a positive change in load, for instance
10 acceleration and/or gravitational force; and a magnitude less than the DC signal when the sensor is affected by a negative change in said load.

As described above, the connected circuit integrates the sensor current. According to preferred embodiments of
15 the invention, this integration can be accomplished by first subjecting the sensor current to a current to frequency conversion. The provision of an added DC signal to provide a combined signal, as described above, is particularly advantageous when used in conjunction with a
20 current to frequency converter, in that the combined signal will always be kept positive and the frequency can be kept proportional to the level of the combined signal.

The current to frequency conversion produces a frequency signal that will be provided to counting means for
25 counting the pulses comprised in the frequency signal. The counting operation will generate the desired integrated value, after compensation for the contribution from the added DC signal, that will be directly representative of the actual acceleration or gravitational force
30 by which the sensor is affected.

The contribution of the added DC signal must, however, be eliminated in order to obtain an integrated signal representing the immediate influence of the load on the sensor. According to an embodiment of the

invention, the contribution of the added DC signal can be removed by deducting in the counter a counter value corresponding to the contribution from the DC signal. After each deduction, the counter value, i.e. the integrated value, will represent the contribution from the sensor current only, and, hence, from the load to which the sensor is affected.

The value to be deducted, herein referred to as a deduction value, can be obtained by disconnecting the sensor from the connected circuit for a given time period, and by registering the pulses in the frequency signal during said time period. Disconnection of the sensor can simply be provided by a switch. When said time period expires, the number of pulses registered during this time period is stored as the deduction value and the operation of the connected circuitry continues, using the updated deduction value, as described above. The operation for obtaining the deduction value can be performed at given time intervals, but is preferably performed when there is no sensor current.

According to another advantageous embodiment of the present invention, the problem in compensating for the contribution of the added DC signal can be solved by providing two parallel signal paths, each path being provided with a separate DC signal, as described above, and including current to frequency conversion means; first switching means, for switching the sensor current between the two signal paths; second switching means, for switching the respective frequency signal from the respective signal path between incrementation and decrementation inputs of an up-down counter; and an up-down counter.

The sensor current is periodically switched between the respective paths, so that the sensor current is half

the time provided to the one path, half the time to the other path. As a result, the converted frequency signal output by each path will half the time comprise the converted combined signal, half the time a frequency conversion of the added DC signal. The converted signal, when including the contribution of the DC signal only, can be seen as an idle frequency signal. Obviously, when the sensor current is zero, a frequency conversion of the combined signal will have the same frequency as said idle frequency signal, regardless of the state of the first switching means.

The frequency signal output by each signal path is periodically switched between incrementation and decrementation inputs of an up-down counter. Said switching is preferably performed in conjunction with the switching of the sensor current between the respective signal paths, so that the path presently receiving the sensor current is connected to the incrementation input of the up-down counter, and that the path presently not receiving the sensor current is connected to the decrementation input of the up-down counter. Hence, the respective frequency signal will increment the counter when including the contribution of the sensor current, and decrement the counter when not including the contribution of the sensor current. Accordingly, the contribution of the respective added DC signals will be completely eliminated and the integrated value output by the up-down counter will be directly representative of the current generated by the sensor. The contribution of the respective added DC signal will be completely eliminated, regardless of any drift of the DC signal over time and regardless of the difference between the DC signals.

According to this embodiment, the counter value, i.e. the integrated value, is constantly being updated

The accelerometer can also be combined with one or more accelerometers having different directions of sensitivity, preferably perpendicular to that of the first accelerometer. Thereby, the possibility of detecting
5 different postures of the patient will increase. For instance, the combination with an accelerometer having a sensitivity in the right-left direction of the patient, would enable distinguishing an upright position from a position where the patient is lying on his/her side.

10 Since the changes in acceleration and gravity connected with changes in posture are relatively slow compared to the changes in acceleration connected with normal physical activity and the device according to the invention takes the leakage of charges from the
15 piezoelectric accelerometer into account, the invention is of particular interest in piezoelectric devices for detecting changes in posture.

As discussed above, the constantly updated integrated value represents the acceleration and/or gravitational force (i.e. the component of the gravitational
20 force in the direction of sensitivity of the accelerometer) to which the accelerometer presently is subjected. The maximum contribution the accelerometer can be subjected to by the gravitational force corresponds to an
25 acceleration of 1 g ($9,81 \text{ m/s}^2$). However, accelerations associated with heavy exercise, such as running, can clearly be in excess of g, sometimes even in excess of 2 g. Therefore, the integrated value will suitably be subjected to further processing in order, e.g., to distinguish
30 between contribution from gravitation and contribution from physical activity.

According to an embodiment of the invention, the constantly updated integrated value can be provided as a digital output signal from the described counting means

to posture evaluation means for determining the posture of the patient. Said posture evaluation means, or means connected between the posture evaluation means and the counting means, performs a digital low pass filtering of the integrated signal. Said low pass filtering, having a preferred cut-off frequency of less than about 1 Hz, preferably about 0,5 Hz, will effectively filter out the contributions of activity, heart beats etc. The low pass filtered integrated signal then can be compared to threshold values for obtaining a posture value indicating the actual posture of the patient. Said posture value can then be provided to control means for controlling the operation of a pacemaker in accordance with the posture of the patient, in a manner known per se.

Likewise, according to a particular embodiment of the invention, the integrated value can also be provided as a digital output signal to activity evaluation means for determining the physical activity of the patient. Said activity evaluation means, or means connected between the activity evaluation means and the counting means, performs a digital band pass filtering of the integrated signal. Said band pass filtering has a preferred lower cut-off frequency of about 1 Hz, and has a preferred upper cut-off frequency of about 10 Hz, preferably about 6 Hz. The band pass filtered integrated signal can then be evaluated in a known manner for obtaining an activity value indicating the physical activity of the patient. Said activity value can then be provided to control means for controlling the operation of a pacemaker in accordance with the physical activity and the posture of the patient.

According to a specific advantageous embodiment of the invention use is made of a piezoelectric accelerometer comprising a two layer beam, one piezoelectric

5

25

As indicated above, the invention also is applicable to other piezoelectric sensors, such as endocardial pressure sensors for measuring the intracardiac pressure.

It is for instance possible to determine changes in posture by means of an intracardiac pressure sensor. The hydrostatic pressure acting on the sensor increases when the patient rises from a prone or supine position to an upright position since the vertical distance upwardly from the sensor within the patient that defines the hydrostatic pressure will increase. The effects of an increase in pressure on the pressure sensor will generally be similar to the effects of acceleration or gravity on an accelerometer of the type described above. The arrangement described above used for evaluating the accelerometer signal thus could be used also for evaluating the signal from the pressure sensor. Since a pacer system normally contains some kind of activity sensor, the pressure signal also additionally could be evaluated by means of the signal from the activity sensor in order to better distinguish the rise in pressure resulting from a change in posture from a change in pressure resulting from a change in activity.

A further use of the arrangement according to the invention is to detect long-term changes or drift in the intracardial pressure by means of a pressure sensor.

Further details and aspects of the invention will become apparent from the following detailed description of embodiments of the invention, reference being made to the accompanying drawings.

Brief description of the accompanying drawings

Figure 1 illustrates in block diagram form a medical implant comprising an apparatus according to the present invention.

Figure 2 illustrates a piezoelectric accelerometer according to a specific preferred embodiment of the present invention.

Figures 3 and 4 illustrates in a block diagram and in a circuit diagram form an apparatus according to a first embodiment of the invention.

Figures 5 and 6 illustrates in a block diagram and in a circuit diagram form an apparatus according to a second embodiment of the invention.

Figure 7 illustrates in pulse diagram form a method according to the present invention.

Figure 8 illustrates in a block diagram an apparatus according to a third embodiment of the invention.

Detailed description of preferred embodiments of the invention

As mentioned above, the invention is applicable to accelerometers and in particular to accelerometers used in connection with pacemakers and similar for detecting changes in posture, and the invention will be described in more detail below with reference to such an accelerometer. Referring to figure 1 there is shown a schematic block diagram of a pacemaker 1 according to the invention. The pacemaker 1 according to the invention includes a piezoelectric sensor (accelerometer) 100, integrating means 200, posture evaluation means 300, a logic circuit 400, and a pulse generator 500. The logic circuit 400 is also connected to activity evaluation means 700, said means being provided with an activity signal originating from the piezoelectric accelerometer 100. The pacemaker 1 is further connected to at least one pacing lead 600 provided with at least one stimulating electrode, said electrode also being used for sensing. The pacemaker 1 further includes processing circuitry for processing the sensing signal(s) from said electrode(s) (not shown). The pacemaker 1 may be arranged for unipolar

or bipolar stimulation in a fashion that is well known to a person skilled in the art.

The piezoelectric accelerometer 100 will now be described with reference to figure 2. The pacemaker 1 of Fig 1 comprises a piezoelectric monoaxial accelerometer 100, consisting of a two layer beam that is at one end fixed via a support 110 to a surface 120, said beam being tilted with respect to the mounting surface 120. The other end, the open end, is provided with a weight 108 that provides a bending or deflecting motion about the fixed end. The upper layer 102 of the beam is made of a piezoelectric ceramic material, the lower supporting layer 104 consists of a high density, high Young's module material. The support 110, the weight 108 and the supporting layer 104 are all made in one piece, the piece being electrically conductive. The layers are adhesively fixed to each other using an electrically conductive adhesive 106. The free upper side of the piezoelectric layer is coated with a thin metallic layer serving as an electrode. The piezoelectric layer 102 is connected to surrounding circuitry via the conductive layer 104 and a lead 112, connected to the metallic layer.

Referring to figures 3 and 5 there is shown the sensor 100 and the integrating means 200 according to preferred embodiments of the present invention. Said integrating means 200 comprises combining means 201, 202, 203 for combining a sensor output current $S(t)$ with a DC signal, thereby obtaining a combined signal $C(t)$ with an offset DC level; converting means 210, 220, 230 for converting the combined signal $C(t)$ into a frequency signal $F(t)$; and counting means 240, 242 for subjecting said frequency signal $F(t)$ to a counting operation for obtaining an integrated signal $I(t)$.

Referring specifically to figure 3, according to a specific preferred first embodiment of the invention, said integrating means further comprises first switching means S_1 , for repeatedly switching said sensor output
5 current $S(t)$ between two parallel signal processing paths, wherein each signal path comprise combining means 201, 202, for combining the sensor output current $S(t)$ with a respective DC signal DC_1 , DC_2 , thereby obtaining a respective combined signal $C_1(t)$, $C_2(t)$, and converting
10 means 210, 220, for converting the respective combined signal $C_1(t)$, $C_2(t)$ to a respective frequency signal $F_1(t)$, $F_2(t)$. The integrating means 200 further comprises second switching means $S_{2,3}$ for switching said frequency signals $F_1(t)$, $F_2(t)$ between inputs of a counting means
15 240. Said counting means 240 being provided for combining the output signals $F_1(t)$, $F_2(t)$ from the two separate signal processing paths, thereby obtaining said integrated signal $I(t)$.

The apparatus according to the specific first embodiment of the present invention will now be described
20 in greater detail with particular reference to the figures 3 and 4. The pacemaker 1 of figure 1 comprises a piezoelectric accelerometer 100, as described above. The integrating means 200 of figure 1 according to this first
25 embodiment comprises a first switching means S_1 in the form of a switch S_1 for switching the output signal $S(t)$ from the piezoelectric accelerometer 100 between two parallel, substantially similar signal paths. The switch S_1 is controlled by a constant, periodic control signal
30 that ensures that the output signal $S(t)$ from the sensor is provided equal time to the respective signal paths. The switching frequency is typically set from about 100 to about 1000 Hz.

The integrating means 200, in each of the signal paths, also comprises combining means 201, 202, for combining the output current $S(t)$ from the piezoelectric accelerometer 100 with a DC signal originating from a current source DC_1 , DC_2 , thereby providing a combined signal $C_1(t)$, $C_2(t)$. The magnitude of the added DC signal DC_1 , DC_2 is greater than the expected maximum value of the accelerometer current from the piezoelectric accelerometer 100.

When the switch S_1 is in a position for switching the sensor output current $S(t)$ to one signal path, the output from the combination means 201, 202 in the respective other signal path includes only the respective added DC signal.

Furthermore, each signal path of the integrating means 200 comprises converting means 210, 220, in the form of an amplifier circuit functioning as a current to frequency converter, for converting the respective provided combined signal $C_1(t)$, $C_2(t)$ into a respective frequency signal $F_1(t)$, $F_2(t)$. Said respective amplifier circuit comprises a first operational amplifier (op amp) 212, 222; a first and a second capacitor 214, 216, 224, 226, four switches S_{11} - S_{14} , S_{21} - S_{24} ; and a comparator 218, 228. The positions of which can be seen in figure 4. The combined signal $C_1(t)$, $C_2(t)$, that is with or without the contribution of the sensor output current $S(t)$, is provided to the first operational amplifier 212, 222.

When said switches S_{11} - S_{14} , S_{21} - S_{24} are in the states shown in figure 4, the first operational amplifier 212, 222 is fed back by the first capacitor 214, 224 and charges said capacitor 214, 224. The comparator 218, 228, shown as a second operational amplifier, compares the charge of the first capacitor 214, 224 to a reference voltage V_{ref} .

When the charge of the first capacitor 214, 224 exceeds the reference voltage, the comparator 218, 228 provides an output signal that produces switching of the switches S_{11} - S_{14} , S_{21} - S_{24} to their second state, thereby
5 discharging the first capacitor 214, 224 and a charging of the second capacitor 216, 226 commences. When the input signal to the comparator 218, 228 once again exceeds the reference voltage V_{ref} , the switches S_{11} - S_{14} , S_{21} - S_{24}
10 switch back again and the procedure is repeated. The output signal of the comparator 218, 228 represents the frequency with which the first and second capacitors 214, 216, 224, 226 are discharged. Thus, the output from the comparator 218, 228 provides a respective frequency signal $F_1(t)$, $F_2(t)$.

15 The rate by which the capacitors are discharged obviously depends of the current level of the combined input signal $C_1(t)$, $C_2(t)$. However, the level of the combined signal $C_1(t)$, $C_2(t)$ is selected so that the frequency of the output frequency signal $F_1(t)$, $F_2(t)$, converted from the combined signal $C_1(t)$, $C_2(t)$, always exceeds the switching frequency for switching the switch S_1 . Actually, half the time, the combined signal will be made up solely of the DC signal DC_1 , DC_2 . When the signal path receives the combined signal $C_1(t)$, $C_2(t)$ solely containing the DC signal contribution, the output from the
20 comparator constitutes an idle frequency signal F_{01} , F_{02} . The frequency of said idle frequency signal F_{01} , F_{02} will be in the magnitude of 10-100 kHz, i.e. by far exceeding the switching frequency for switching the switch S_1 .

30 The integrating means further comprises second switching means $S_{2,3}$ in the form of a first switch S_2 and a second switch S_3 , for switching the output frequency signal $F_1(t)$, $F_2(t)$ from the respective signal path between the respective positive and negative inputs of a

counting means 240. The first and second switch S_2 , S_3 operate in a reverse manner so that when the first switch S_2 connects one signal path to the positive input of the counting means 240, the second switch S_3 connects the other signal path to the negative input of said counting means 240. The switches S_2 , S_3 are controlled by the same constant, periodic control signal noted above with respect to controlling the switch of the first switching means S_1 , the switching frequency being 20 Hz. Thus, the respective signal paths are connected to one input of said counting means 240, i.e. the positive input, when the path is currently receiving the sensor output current $S(t)$, and, accordingly, is connected to the other input, i.e. the negative input, when the path is not receiving the output signal $S(t)$ from the piezoelectric accelerometer 100.

The integrating means 200 further comprises a counting means 240 in the form of an up-down counter for counting the pulses of the frequency signal $F_1(t)$, $F_2(t)$ produced by the above described comparator, thereby obtaining the integrated signal $I(t)$. The up-down counter 240 includes a positive input for incrementing the counter 240 and a negative input for decrementing the counter 240. Each output pulse included in the frequency signal $F_1(t)$, $F_2(t)$ output by the respective comparator 218, 228 produces an incrementation or a decrementation of the counter 240, depending of the state of the switches S_2 and S_3 .

The pacemaker 1 shown in figure 1 further comprises posture evaluation means 300 for evaluating the integrated signal $I(t)$ and obtaining a value directly representative of the physical posture of the patient. The digital low pass filtering with a cut-off frequency of 0,5 Hz is performed by said posture evaluation means 300,

or by means not shown connected between the integration means 200 and the evaluation means 300. The posture evaluation means further compares, at certain predetermined time intervals, the integrated, digitally low pass
5 filtered signal to predefined threshold values. The evaluation means 300 provides a signal to the logic circuit 400 indicative of the following physical posture states when the accelerometer is subjected to a gravitational force contribution corresponding to an
10 acceleration of:

- 1 g, patient lying in a prone position;
- 0 g, patient being in an upright position; and
- 1 g, patient lying in a supine position.

15 The evaluation means 300 can also provide a signal indicative of uncertain posture, e.g. when the posture of the patient changes from a supine to standing position.

According to a specific embodiment of the invention, the pacemaker 1 also comprises activity evaluation means
20 700 for providing a signal to the logic circuit 400 indicative of the current patient activity. In accordance with the posture evaluation means, the integrated signal $I(t)$ is subjected to a digital band pass filtering for removing signal contribution that is not related to
25 patient physical activity. The upper and lower cut-off frequencies of said digital band pass filtering is 1 Hz and 6 Hz, respectively. The digital band pass filtering per se can be performed in a manner well known to the person skilled in the art, and will therefore not be de-
30 scribed in greater detail. The output signal from said activity evaluation means 700 is then provided to the logic circuit 400.

The pacemaker 1 shown in figure 1 further comprises a logic circuit 400 and a pulse generator 500 for con-

trolling, regulating and delivering pacing pulses, via the pacing leads, to the atrium and/or ventricle of the heart. Said controlling is performed at least on the basis of the posture and activity of the patient in a manner known to the person skilled in the art. It should be understood that means and circuits required for the conventional operation of a pacemaker according to the state of the art is included in the pacemaker according to the present invention, although not shown or described herein.

With particular reference now to figure 7, there is shown in diagrammatic form how an acceleration contribution, in an idealised form for explanatory reasons, is represented by the integrated signal. The pulse diagram consists of six different signals (A-F) divided into five time periods by the dotted lines (1-5).

A is the idealised contribution of the gravitation component, in the sensitivity direction of the accelerometer, to which the accelerometer is affected. In a true case, this would be superimposed by the activity and noise contributions constantly present.

B is the current generated by a piezoelectric accelerometer that is subjected to the gravitation component according to A, i.e. the sensor output current $S(t)$. This current is proportional to the derivative of the acceleration.

C is the control signal controlling the switches S_1 - S_3 , i.e. the switching of the sensor output current $S(t)$ between the parallel signal paths and the switching to the up-down counter.

D are the output signal pulses delivered by the comparator 218 of the upper signal path, and E are the pulses delivered by the comparator 228 of the lower signal path, in the manner described above. Said respective

pulses control the respective switches S_{11} - S_{24} and triggers the incrementation and decrementation of the up-down counter 240. The difference in pulse width is only to illustrate the fact that a difference in the magnitude of the respective DC signals DC_1 , DC_2 does not effect the performance of the integrating means. The contributions of the DC signals DC_1 , DC_2 are completely eliminated.

F is the resulting integrated signal $I(t)$ registered in the counter 240 and provided to the posture evaluation means 300.

During the time intervals 1-2, 3-4 and 5-6, the sensor output current $S(t)$ is switched to the upper signal path, the comparator of which is switched to the positive input of the up-down counter 240. Accordingly, during these time intervals, signal D increments and signal E decrements the up-down counter 240. Consequently, during time periods 2-3 and 4-5, the sensor output current is switched to the lower signal path L, signal E increments the counter and signal D decrements the counter.

As can be seen in figure 7, the level of the integrated signal $I(t)$ provided by the counter 240 closely match the gravitation component to which the piezoelectric accelerometer 100 currently is subjected. Hence, the output of the integrating means according to the invention provides a direct absolute value representing the current deflection of the accelerometer beam and, hence, the current gravitation (or acceleration).

Now, with particular reference to figures 5 and 6, an apparatus according to an alternative second embodiment of the invention will be described. According to this alternative second embodiment, the integrating means 200 shown in figure 1 comprises only one signal path, thereby precluding the need for first and second switching means for switching the sensor output current $S(t)$

between separate signal paths. As noted above, the integrating means 200 comprises combining means 203, converting means 230, and counting means 242. The converting means 230 are in the form of an amplifier circuit, said
5 amplifier circuit comprises a first operational amplifier 232; a first and a second capacitor 234, 236, four switches S_{31} - S_{34} ; and a comparator 238. The functions of the combining means 203, the converting means 230, and the components comprised in the converting means 230, are
10 similar to the functions of the corresponding means and components described above with particular reference to the figures 3 and 4, and will therefore not be described in greater detail.

The counting means 242, according to this second
15 embodiment, further comprises a counter for counting the pulses of the frequency signal $F(t)$, produced by the comparator 238. As described above, the DC signal is superimposed on the sensor output current $S(t)$. The contribution from the DC signal is removed by deducting, at
20 predefined time intervals, e.g. every 1-10 ms, a counter value corresponding to the contribution from the DC signal. The integrated signal $I(t)$ output from the counter is updated after each deduction, and the integrated signal $I(t)$ is representative of the acceleration or gravi-
25 tation.

The counter value to be deducted, a deduction value, is obtained by disconnecting, at certain given time intervals, e.g. 1 hour, for a given time period, e.g. 1 sec, the piezoelectric accelerometer 100 from the combin-
30 ing means 203 by the opening of a switch (not shown) positioned between the accelerometer 100 and the combining means 203. When the time period expires, the number of pulses registered during this time period is stored as the new deduction value, the switch is closed, and the

operation of the integrating means 200 continues, with the updated deduction value, as described above.

The pacemaker 1, according to this second embodiment of the invention, also comprises posture evaluation means 300, a logic circuit 400, a pulse generator 500, and activity evaluation means 700, in the same manner and with the same functions as described above with reference to the first embodiment of the invention.

In a third embodiment the posture may be evaluated with an intracardiac pressure sensor. The hydrostatic pressure acting on the sensor increases when the patient rises from a prone or supine position to an upright position since the vertical distance upwardly from the sensor within the patient that defines the hydrostatic pressure will increase. The effects of an increase in pressure on the pressure sensor will generally be similar to the effects of acceleration or gravity on an accelerometer of the type described above. The arrangement described above used for evaluating the accelerometer signal thus could be used also for evaluating the signal from the pressure sensor. Since a pacer system normally contains some kind of activity sensor, the pressure signal also additionally could be evaluated by means of the signal from the activity sensor in order to better distinguish the rise in pressure resulting from a change in posture from a change in pressure resulting from a change in activity.

Referring to figure 8 there is shown a schematic block diagram of a pacemaker 1 according to the invention including a piezoelectric sensor (pressure sensor) 100', integrating means 200, posture evaluation means 300', a logic circuit 400, and a pulse generator 500. The logic circuit 400 is also connected to an activity sensor 800. The features in this drawing that are identical to

features in Fig 1 have the same reference numerals as in Fig 1. The pacemaker 1 is further connected to at least one pacing lead 600 provided with at least one stimulating electrode, said electrode also being used for
5 sensing. The pacemaker 1 further includes processing circuitry for processing the sensing signal(s) from said electrode(s) (not shown). The pacemaker 1 may be arranged for unipolar or bipolar stimulation in a fashion that is well known to a person skilled in the art.

10 The pacemaker 1 shown in figure 8 thus also comprises posture evaluation means 300' for evaluating the integrated signal $I(t)$ and obtaining a value directly representative of the physical posture of the patient. The digital low pass filtering with a cut-off frequency
15 of 0,5 Hz is performed by said posture evaluation means 300', or by means not shown connected between the integration means 200 and the evaluation means 300'. The posture evaluation means further compares, at certain predetermined time intervals, the integrated, digitally low
20 pass filtered signal to predefined threshold values. The evaluation means 300' provides a signal to the logic circuit 400 indicative of different physical posture states, e. g. an increase of about 20 mm Hg would indicate an upright position. Although it may be conceivable to
25 evaluate the physical activity of the patient by means of the short-term characteristics of the pressure signal per se in order to better distinguish the rise in pressure resulting from a change in posture from a change in pressure resulting from a change in activity, it is
30 preferred that the pressure signal also additionally is evaluated by means of the signal from a separate activity sensor, such as activity sensor 800. Separate activity sensors are standard features in pacers. It should be noted that in the above embodiment relating to an

accelerometer, this accelerometer primarily is an activity sensor and therefore there is no further need of a further sensor to check whether a signal indicating a change of posture is a result of a sudden activity or
5 not.

In similarity to the accelerometer-based activity signal used in the two first embodiments described above for determining the posture, the pressure signal also contains components that varies comparatively rapidly
10 with the heart beats. These components would correspond to the constantly present activity and noise contributions superimposed on signal A in Fig 7 and would be superimposed on a pressure signal reflecting the hydrostatic pressure that in turn corresponds to the
15 signal A in Fig 7.

The design of the circuits otherwise is identical to the circuits used above in connection with the above embodiments for an accelerometer.

The intracardiac pressure may however also comprise
20 a component that varies slowly over relatively long time periods of time, resulting in a very low variation per time unit. These long-term variations can also be detected by means of the above third embodiment of the invention. This is also indicated in Fig 8 with the
25 reference numeral 300" denoting a long-term trend of change of pressure analysis means. This means is however in principle identical to the posture detecting means 300 and 300', the main difference being that the low-pass filter in the trend analysis means has a cut-off
30 frequency that is considerably lower than the cut-off frequency in the filters in the evaluation means 300 and 300' and may for instance be 0.05 Hz.
